CHAPTER 4

ANTHROPOMETRIC STATUS

INTRODUCTION

Physical growth is regulated primarily by two factors, namely genetics and the environment\(^1,2\). In terms of the latter, the quantity and quality of food available are the main determinants of growth rate. In the health and related professions, anthropometry is generally used to determine the nutritional status of individuals and populations, and by implication the availability of proper food. The relative ease with which the weight and height of an individual can be determined and compared with those of a well nourished individual of similar sex and age, lends the technique of anthropometry to being widely used in the assessment of the nutritional status of individuals and populations. The technique is also useful in the prediction of morbidity and mortality, the assessment of the effects of poverty as well as in the monitoring and evaluation of intervention programmes.

Macronutrient components of foods like protein, carbohydrate and fat, which are the sole contributors to energy intake, are the principal determinants of growth rate. For this reason, the anthropometric determination of nutritional status is indicative mainly of the availability of protein and energy foods.

UNICEF has estimated that 190 million children younger than five years of age are chronically malnourished and are trapped early in life in a pattern of ill health and poor development\(^1\). In 1987, the United Nations sub-committee on nutrition and the World Health Organisation estimated that one-third to two-thirds of children in developing countries show some degree of growth retardation\(^2\). It is insufficiently appreciated that most of the excess infant mortality is due to hunger; even when the immediate cause of death is due to diarrhoea, pneumonia, measles or other infectious disease, death would have rarely occurred in a well nourished child.

Over the past two decades, a number of studies on preschool children have established the relatively high prevalence of protein-energy malnutrition (PEM) in preschool children\(^3,16\) in the country. The percentages of under 5 year old children being underweight range from 21% in the Dias divisional council\(^6\), 15% in Botshabelo\(^13\) to 8% in rural South Africa\(^11\).

Depending on its severity, the adverse effect of PEM on childhood mortality, impaired intellectual development as well as propensity to infections is well documented\(^17-26\). It is also widely accepted that PEM is associated with a number of micronutrient deficiencies of which vitamin A, iron and iodine are the most common, and the restitution of these micronutrients to normal levels has the most dramatic effects on general health improvement\(^2\). For these reasons, the anthropometric assessment of children was incorporated in this study.
**METHODOLOGY**

**Age and Gender Determination**

The date of birth was recorded from the Road to Health Card or birth certificate, wherever possible. Where this was not possible, respondent's recall was used. Gender was recorded.

**Weight Determination**

Using electronic scales, weight was determined on all the children. The average of two readings was used. The following method was employed:

- The scale was placed on an even, uncarpeted area and was leveled with the aid of its in-built spirit level.

- After the scale was switched on, the fieldworkers had to wait for the zero indication (0,0) as well as the stable indicator (0 in the top left hand corner of the display panel) to appear.

- The children were weighed (preferably after emptying their bladders) and with the minimum of clothing:
  - diapers only for babies (dry only)
  - underclothes for older children.

- The child was placed on the scale, standing still and upright in the middle of the platform, facing the fieldworker, looking straight ahead with their feet flat and slightly apart until the reading was taken.

- After the reading was recorded in the space provided on the questionnaire, the child was removed from the scale. The weight was recorded to the nearest 100g.

- After the child stepped down from the scale, the fieldworkers had to wait for the zero reading to appear on the digital display before repeating the procedure once.

- The two readings could not vary by more than 100g. If they did, the scale had to be checked for accuracy and the procedure had to be repeated until the correct weight was obtained.

- When the child/baby was not able to stand alone on the scale, the following method was employed:
  - The first two steps above were followed.
  - The mother/caretaker was weighed first (without heavy clothing and shoes).
  - Then the zero/reset button was pressed and the fieldworkers had to wait for the zero reading (0,0) to appear on the digital display.
The baby was then placed in the mother’s arms and the reading taken and recorded.

The mother and child were then taken off the scale, and when the zero reading appeared again on the display the procedure was repeated once.

### Height Determination

#### Children younger than 2 years

The supine height in these children was determined by means of a measuring board, which was specially constructed for the survey.

- Two readings were taken and the measurement was repeated if the two readings varied by more than 0.5 cm.

- The measuring board was placed on an even, uncarpeted area.

- Care was taken to ensure that the measuring board was functional and the footboard had no undue loose movement.

- The child was placed on the measuring board lying on his/her back with the crown of the head touching the fixed headboard and the shoulders touching the base of the board. One fieldworker was needed to hold the child in this position.

- A second fieldworker ensured that the child’s heels touched the board and the legs were straightened (knees not bent), before the footboard was slid against the soles of the child’s heels. The measurement was taken on the inside of the footboard to the nearest 0.1 cm.

- The measurement was recorded in the space provided on the questionnaire and the procedure was repeated once.

#### Children 2 years of age and older

The standing height of these children was taken by means of a stadiometer. Two readings were taken and the measurement was repeated if the two readings varied by more than 0.5 cm.

- The stadiometer was placed on an even, uncarpeted area.

- The child’s shoes were removed.

- The child was positioned as follows:
  - facing the fieldworker.
o shoulders relaxed, with shoulder blades, buttocks and heels touching the measuring board.

o arms relaxed at sides.

o legs straight and knees together; and

o feet flat, heels touching together.

• With the child looking straight ahead (Frankfurt plane), the headpiece was slid down until it touched the crown of the head.

• The reading was taken to the nearest 0.1cm.

• The measurement was recorded in the space provided on the questionnaire and repeated once.

**Criteria Used for the Assessment of Anthropometric Status**

The data were compared with those of the National Center of Health Statistics of the USA\textsuperscript{27} using Epi Info version 6.02\textsuperscript{28}. Ages were re-calculated as "biologic" ages, i.e. dividing the year into 12 equal segments. For each child, a z-score (i.e. the number of standard deviations (SDs) from the reference population median) was calculated for weight-for-height, weight-for-age and height-for-age. If the z-score for weight-for-age or height-for-age was less than -6SDs or greater than +6SDs, or if the z-score for weight-for-height was less than -4SDs or greater than +6SDs, then the record was first verified for accuracy of data entry. Where an error had occurred on data entry, this was corrected; where no error could be detected, the indicator with such an extreme z-score was set to missing and, therefore, excluded from the analysis. The number of records with such extreme z-scores was 293 for weight-for-height, 13 for weight-for-age and 291 for height-for-age.

For just under 10% of the sample, the age of the child was given rather than the date of birth. For half of these, the age in complete years was provided rather than years and months. In order to assess the effect of including this latter group in the analysis, the three anthropometric indicators were compared using all available results and then excluding this group. The results, when excluding and including this group were respectively: weight-for-height 2.6 and 2.7; weight-for-age 9.3 and 9.5; height-for-age 23.5 and 23.5. The good agreement of these results led to the decision to include all available data in the analysis.
RESULTS

At the national level, the average percentage of preschool children falling under -2SDs weight-for-height was 3%, whereas only 0.4% of the children were below -3SDs (Table 4.1). Free State, North West, Northern Province and Eastern Cape had the highest percentages of children under -2SDs weight-for-height, with the lowest figures in KwaZulu/Natal and Gauteng (Fig 4.1). These findings indicate that wasting is not a serious problem in preschool children in South Africa.

Northern Cape, Free State, North West, Northern Province and Eastern Cape had the highest percentages of children below -2SDs weight-for-age with Gauteng and KwaZulu/Natal having the lowest values (Table 4.1; Fig 4.1). The average value for South Africa was 9%. The percentage of children below -3SDs weight-for-age was 1%.

In terms of a national average for height-for-age, 23% of children were under -2SDs indicating that stunting is a major problem in South Africa (Table 4.1). In the Northern Province 13% of the children were below -3SDs of the expected height-for-age, which is indicative of severe stunting (Fig. 4.1). The national average percentage for stunting (23%) is more than twice the value for being underweight (9%). Rural areas had a higher percentage of children below -2SDs weight-for-age (11%) than the urban areas (7%) (Table 4.1). A similar pattern was seen for height-for-age and, to a lesser extent, weight-for-height (Table 4.1; Fig. 4.1). These observations support previous findings that rural communities are nutritionally at a greater disadvantage than those in the urban areas. The percentages of children below -2 or -3SDs weight-for-height, weight-for-age and height-for-age did not vary significantly with age, except for the 6-11 month old children who had a lower prevalence for low weight-for-age and height-for-age (Table 4.2; Fig. 4.2).

Figure 4.3. Anthropometric status by maternal education
The prevalence of wasting was similar across all types of housing (Table 4.3) and levels of maternal education (Table 4.3; Fig. 4.3). However, the prevalence of being underweight tended to be higher in children living in informal housing and was the lowest for children whose mothers were well educated. Significantly though, the prevalence of stunting was the highest in children living in traditional or informal housing and had poorly educated mothers.
In the present study, anthropometrically, a low [(<5%)29] prevalence of wasting, a low [(<10%)29] prevalence of being underweight and a medium [(20.0-29.9%)29] prevalence of stunting have been documented at the national level.

Nutritional status, however, varied considerably between urban and rural populations and among provinces. The prevalence of wasting, although low [(<5%)29], varied from 0.7% in KwaZulu/Natal to 4% in North West and Free State; the prevalence of being underweight varied from a low [(<10%)29] of 4% in KwaZulu/Natal to a medium [(10.0-19.9)29] of 16% in Northern Cape, almost a fourfold difference. Similarly, there was almost a threefold difference in the prevalence of stunting between Gauteng (11%) and Northern Province (34%), the latter being a high [(30.0-39.9%)29] prevalence. Previous studies6,13 of preschool children have reported a prevalence of 16% and 29% for underweight and stunting, respectively, compared to 11% and 29% in this study; furthermore, in the Free State the previously reported prevalence of 15% underweight and of 36% stunting in preschool children is also similar to the present findings (14% and 29% respectively). Furthermore, the study by the Regional Health Organisation of Southern Africa (RHOSA) on rural children reported a prevalence of 8% underweight and of 25% stunting in preschool children11. These values are in reasonable agreement with the average values of 9% underweight and of 23% stunting found in the present study. The present findings, therefore, indicate that malnutrition continues to be a significant problem in the country, especially in the rural areas.

In 1994, a national study in children starting school involving 364 magisterial districts, 3 347 primary schools and 97 790 children, 9.0% of children were underweight and 13% stunted30. The study included 12% of children who were younger than 6 years of age, 30% between 6 and 7 years and 31% between 7 and 8 years of age; these age groups partly overlap with those of the present study. The prevalence of being underweight or wasted in both studies (< -2SDs) is very similar (9% underweight and 3% wasted in this present study vs 9% and 3% respectively), whereas the prevalence of stunting (< -2SDs) is almost double in the present study (23% vs 13% in the school survey). Within the obvious time and age group limitations of such a comparison, it would appear that the prevalence of malnutrition in the country continues to be unacceptably high and is indeed a cause of grave concern. Although the very young (6-11 months) appear to be less severely affected by stunting than the older children (>12 months), nevertheless, of equally grave concern, is the increase (Table 4.2) in the prevalence of being stunted with age, a finding that has important implications in terms of formulating and implementing intervention programmes.
In comparative terms (Table 4.4)1, preschool South African children appear to have a more favourable nutritional status than children elsewhere in Africa, Central and South America and in the Indian peninsula. However, although the average South African prevalence of anthropometric indices appears favourable, it is certainly no cause for complacency; it is indeed a cause of grave concern and it calls for immediate action, especially in those areas where the prevalence of stunting exceeds 20%, i.e. in six of the nine provinces. The latter, together with the presence of deficiencies of vitamin A, iron (and possibly iodine), represents a very considerable risk of infection, morbidity and mortality in the population studied. As such, the improvement of the nutritional status and health care services for preschool children should undoubtedly be seen as a national priority and afforded the full benefits of the government's Reconstruction and Development Programme.

The prevalence of stunting is known to reflect socioeconomic standards. It is also known that the most adverse impact of undernutrition on the growth of children occurs in the 6-24 month old age group31,32. The prevalence of stunting can be significantly reduced, but by no means eliminated33-36, with improvements in socioeconomic conditions and better and more accessible health care facilities. This suggests that the country is likely to be faced with the problem of stunting for some significant number of years in the future; as such, appropriate intervention programmes are clearly needed to address this problem on an urgent basis. In this regard, socioeconomic development is of paramount importance31-36; improvement of nutritional status is also significantly, if not equally, important37,38. Importantly though, food supplementation schemes are most likely to have maximal benefit, in terms of reversing stunting, when they are provided during the period of maximum growth deficits, namely to the very young children; for instance, each 100
Kcal/day in supplementary feeding during the first year of life is reported to be associated with approximately 9 mm in additional length gain as compared with 5 mm, 4 mm and no impact of linear growth at all when the same supplement is given during the second, third or fourth year of life, respectively. Similarly, in a more severely malnourished population, each 170 Kcal/day supplementary feeding is associated with an additional growth of 2,8, 1,7 and 1,1 cm in 1-2, 2-4 and 4-5 year old children, respectively.

It is insufficiently appreciated that the composition of the supplementary foods is as important as providing such foods. Although adequate energy intake is important, its role is often overemphasised; indeed, neither energy nor any of the known nutrients, on their own, have been shown to affect linear growth consistently. Within the context of developing countries, it is generally accepted that an inadequate energy intake is likely to be associated with inadequate intake of other nutrients, especially micronutrients, as well as with poor dietary quality. Recent evidence from a multinational (Mexico, Kenya and Egypt) longitudinal study indicates that although stunting occurred soon after birth in all three countries, as it has also been shown to be the case in the present study, energy deficiency was a problem only in Kenya; all three populations studied, however, had poor dietary quality and multiple micronutrient deficiencies. The inclusion of those micronutrients known, in the case of deficiency, to adversely affect linear growth, therefore, should be included in any supplementary foods.
RECOMMENDATIONS

The findings of the present national study indicate that one in ten of all preschool children is underweight and almost one in four is stunted. This translates into approximately 660 000 preschool children being identifiably malnourished and 1 520 000 being stunted because of long-term malnutrition.

SAVACG offers its assistance in the implementation of those recommendations for which it has the relevant expertise and infrastructure. In terms of the recommendations made in this chapter, SAVACG can assist with recommendations 4.1.1, 4.1.3, 4.1.4, 4.2.3, 4.2.5, 4.2.6 and 4.2.7.

4.1 Short-term

4.1.1 Stunting should be addressed within the proposed framework of the Nutrition Committee\(^4\) regarding an integrated nutrition strategy for South Africa which must be compatible with the ethos and principles of the government's Reconstruction and Development Programme for socioeconomic upliftment. Essentially, the strategy includes:
- i) health facility-based nutrition programmes,
- ii) community-based nutrition programmes,
- iii) nutrition promotion, communication and advocacy,
- iv) national nutrition surveillance for growth monitoring,
- v) legislation, policy and regulations to improve nutrition, and
- vi) human resource development. These aspects will not, therefore, be repeated or expanded upon in the rest of the report.

4.1.2 The findings of the present study clearly identify the preschool child, especially the very young (< 2 years of age), as a prime target group for nutritional intervention, and the mother for nutrition education. At present, both these aims should be concurrently achieved within the existing health facility-based and community-based nutrition programmes.

4.1.3 The supplementary foods that are currently, or will be, provided should not simply concentrate on energy content but also on dietary quality and micronutrient composition.

4.1.4 All children with anthropometric parameters that fall below -2SDs should be targeted.

4.2 Medium- and Long-term

4.2.1 In the longer-term, the provision of supplementary foods is seen as an interim measure. The need for continued supplementary feeding must be weighed against socioeconomic development. As the latter increases, the former should be phased out.
4.2.2 Due consideration should be given to creating creche facilities within the community and at the workplace, especially in provinces with a high prevalence of stunting and in disadvantaged communities within provinces which have a high prevalence. Income generating activities could be linked to these structures.

4.2.3 Similarly, health facility-based rehabilitation centers should be established for the intensive treatment, supervision and follow-up of severely malnourished children. The mothers of malnourished children, apart from being educated, can also concurrently engage in income generating activities.

4.2.4 The financial aspects of recommendations 4.2.2 and 4.2.3 should be interpreted and viewed in the light of the current budget for and cost-effectiveness of the Primary School Nutrition Programme.

4.2.5 The Directorate of Nutrition should enable both universities and research organisations to conduct research on the monitoring and evaluation of any such schemes that are implemented. In this regard, particular attention should be given to the long-term benefits afforded to children by such schemes.

4.2.6 The Directorate of Nutrition should establish a Consultative Group, such as SAVACG, specifically mandated to monitor growth as well as the prevention, identification and treatment of malnutrition.

4.2.7 An anthropometric assessment of preschool children should be repeated in three years with a view to assessing progress achieved.
